

A. The model assumes observed data originates from a latent variable $\tilde{Y} \sim N(0, 1)$. If there are multiple conditions, the $\tilde{Y}$ corresponds to baseline, and the $\tilde{Y}_j$ for other conditions are estimated parameters.

B. The model estimates thresholds (τ_k) from the data (visualized using mean, and 50% and 95% CIs)

C. As y-axis represents $F(x)$, $Pr(y_i = k)$ is the difference on the y-axis between where Y intersects τ_k and τ_{k-1}
